## ABSTRACT

We present findings from a study conducted in a pediatric trauma center to elicit design requirements for the *TraumaPen* system—a mixed paper-digital interface using a digital pen and a wall display—for supporting situation awareness during trauma resuscitation. We first describe the field research that informed the initial system prototype and then present findings from two studies in which the prototype was used to further explore the application area. The results from these studies showed the potential for digital pen technology in supporting teamwork in the dynamic and safety-critical setting of the trauma bay but also revealed several limitations of this technology. We conclude by discussing challenges and requirements for the use of paper-digital interfaces in assisting fast-paced, collaborative work processes such as trauma resuscitation.

## Author Keywords

Healthcare, medical records, trauma resuscitation, pen-based computing, situation awareness, collocated teams.

## ACM Classification Keywords

H5.m. Information interfaces and presentation (e.g., HCI):  
Miscellaneous.

## General Terms

H.5 [Information Interfaces and Presentation]: User Interfaces.

## INTRODUCTION

Trauma remains the leading cause of death and disability in children and young adults worldwide. Because early care after a major injury has an important impact on the patient outcome, the initial management of injured patients in the emergency department (*trauma resuscitation*) must be efficient and effective. During resuscitation, an interdisciplinary team of medical specialists (*trauma team*) must identify and treat potentially life-threatening injuries, often with the need for a critical decision about once every

minute. Awareness of events in the room and their progression is thus essential to efficient trauma care. To maintain situation awareness—obtain and interpret information about the patient, the actions of other team members and the environment, and then use this information to predict changes in each—team members must attend to concurrent tasks, changing plans and personnel, and variable patient status. Information sharing is now only minimally supported by technology and trauma teams primarily rely on collective memory and verbal communication [17]. Furthermore, verbally reported information is often inaudible and inaccurately transmitted to other team members [4]. Although patient status and treatment plans are recorded in real time on a paper flowsheet by the nurse recorder, this record mainly serves an archival role and offers minimal support for real-time work [16]. We believe that the role of the flowsheet can be expanded to improve information use during resuscitation.

Our long-term research goal is to develop information and communications technologies (ICT) to improve situation awareness during dynamic safety-critical teamwork, such as trauma resuscitation. To elicit design requirements for such a system, we developed a prototype called *TraumaPen* and evaluated its feasibility in supporting trauma teamwork. The initial prototype design was based on findings from in-depth field studies at two US Level 1 (highest) trauma centers and followed an iterative design approach. To support situation awareness, we used a digital pen for real-time data capture and a large wall display for real-time data presentation. In doing so, we exploit the familiarity of current, low-tech documentation techniques in the trauma bay to introduce computational and communication mechanisms to improve information accessibility for members of the trauma team.

In this paper, we describe our requirements gathering and analysis process using the *TraumaPen* prototype and the findings from two evaluation studies in which the prototype was used to assess system feasibility. Design solutions proposed here are initial steps toward reaching our long-term research goal. Introducing ICT in a domain such as trauma resuscitation, in which the use of paper forms has persisted because computer entry is often not expeditious enough, is a complex problem that may take years to solve. We believe that HCI researchers and practitioners will

*Technical Report, September 2011*

benefit from our intermediate results. Our iterative design and evaluation process revealed several design challenges for trauma resuscitation domain and showed that some claims made about digital pen technology in other settings are not supported in the trauma bay. We discuss these challenges as well as insights about the use of information in time-critical work that need to be addressed in system design. The key contributions of this paper are:

- A prototype system to support situation awareness, designed and evaluated iteratively with involvement of trauma team members.
- Identified requirements and challenges for technologies to support situation awareness in a domain characterized by rapid information acquisition and processing.

### Digital Pen Technology & Large Displays

Despite increasing use of advanced technologies in healthcare [3,12,20], trauma resuscitation remains one of the few medical settings with minimal ICT support, primarily depending on paper artifacts. The continued use of paper is a barrier to using real-time digital information processing for improving patient care and reducing medical errors. Several attempts have been made to introduce ICT in resuscitation areas, but they have not yet yielded feasible solutions [9]. The key reasons for the lack of success include the challenge of capturing and manually entering data from diverse sources in a fast-paced environment and the difficulty of synthesizing output and recommendations.

Recent technological advances have begun to bridge the paper-digital gap. Rather than replacing paper with digital devices, new approaches have focused on augmenting paper and enabling connections between paper documents and information systems [11]. One such approach uses a digital pen as an input device that captures the location and time of all pen marks for digital analysis. Digital pen technology retains the affordances of paper while allowing users to exploit digital interfaces in domains ranging from text processing [23], to field biology [27], to military operations [6]. The use of digital pens has also been studied in medical settings as a method for supporting archiving [8,22,28] but has not been evaluated yet as a tool to aid collaborative work in a setting that requires the rapid acquisition, sharing and interpretation of information.

Large displays have been used to support situation awareness, task coordination, collaboration and information sharing [7,21,24]. Bardram et al. [3] deployed large interactive displays in a surgical ward to support spatial, temporal, and social awareness. Others have examined low-tech solutions such as whiteboards [25,26]. These studies have shown that status boards and wall displays can help support work that is distributed over people, time and space by facilitating task coordination and management, resource planning and tracking, synchronous and asynchronous communication, and problem solving.

Findings from previous work using digital pens and large displays in medical settings led us to consider the potential of coupling digital pens with wall displays to support situation awareness during trauma resuscitation. Digital pen technology has been studied in several medical settings, yet its feasibility has not been evaluated in unpredictable and dynamic settings such as resuscitation areas. Similarly, digital pens have been used for dynamic presentation of digital slides [19] and for translating paper-based interactions onto large interactive whiteboards [5]. Yet, they have not been studied for the purposes of supporting situation awareness through real-time data presentation in dynamic work environments. Coupling digital pens with wall displays is a novel and potentially effective mechanism for supporting teamwork in work settings characterized by rapid information acquisition and processing.

### FROM FIELD RESEARCH TO DESIGN REQUIREMENTS

Our initial design of the TraumaPen system was based on findings from in-depth field studies conducted over the past four years at two US Level 1 trauma centers—an urban teaching hospital in the Northeast and an urban pediatric teaching hospital in the mid-Atlantic region. Both centers have similar trauma team composition and follow the standard protocol for patient evaluation and treatment [1]. A trauma team typically consists of an attending surgeon, a team leader (a surgical fellow or a senior resident), a physician doer (a junior resident), an anesthesiologist, a respiratory technician, a primary nurse, a medication nurse, a technician, and a nurse recorder. Patient evaluation protocol consists of a rapid primary survey of major physiological systems (Airway, Breathing, Circulation, and Disability), detailed secondary survey, and the initiation of definitive care. The two centers treat over 1,000 trauma patients per year each, most with injuries from car accidents, falls, and gunshot or stab wounds.

### Observed Work Practices and Problems

Field research involved observations of 115 actual resuscitations, analysis of 255 videotaped resuscitations, semi-structured interviews with 20 trauma team members, and shadowing trauma personnel. Below we highlight key observations from our field studies that motivated and informed the initial design of the TraumaPen system. Detailed descriptions of methods and findings are published elsewhere [16,17].

#### *Information Overload*

Over the course of trauma resuscitation, teams manage large amounts of information about patient status and the team's activities. This information becomes available in a short time period (on average 20 to 30 minutes) and in a continuous data flow from sources both inside and outside the hospital. Our analysis of inquiries posed by team members revealed over 60 different types of information needed in a typical event. The most frequent information types included patient personal information, patient medical

**Figure 1: Paper-based trauma flowsheet (simplified from the original form for clarity).**

history, details about the mechanism of injury, vital signs, status of major physiological systems, and details about treatments and equipment used. Some information was needed at all times, while the need for other information faded over time. For example, mechanism of injury was important for making the initial decision about the patient treatment; airway status was needed during initial evaluation; age and weight were needed throughout the event to determine medication and fluid dosage.

## *Reliance on Verbal Communication and Collective Memory*

Team activities and patient conditions are conveyed verbally and recorded on a paper flowsheet to facilitate subsequent medical care and post-event team evaluation, but not real-time decision-making (Figure 1). Our field studies have shown that team leaders seldom look up the flowsheet information to make decisions. Leaders reported that approaching the recorders' desk and finding information in the densely populated flowsheet is inconvenient and takes time. Another reason is that much information about the patient status and team activities is available by looking at or around the patient. For instance, one can know if the patient is intubated by glancing at the patient's face. In addition, team members performing the tasks are required to inform the leaders about their status using verbal reports. Because there are no mechanisms by which patient information is currently accrued to allow for rapid integration and analysis of patient data, trauma leaders mainly rely on verbal communication and collective memory for information access. Verbal reports, however, are often unreliable as team members forget to report their status. More important, dynamic information, such as past vital signs, or the amount of fluid and medications already administered, cannot be inferred by looking at the patient-bed area. This is where the team leaders expressed the need for external memory aids to support decision making and the team's situation awareness.

### *Supportive Roles of the Recorder and Trauma Flowsheet*

To ensure accurate documentation of the large number of evaluation and treatment steps, the recording task is

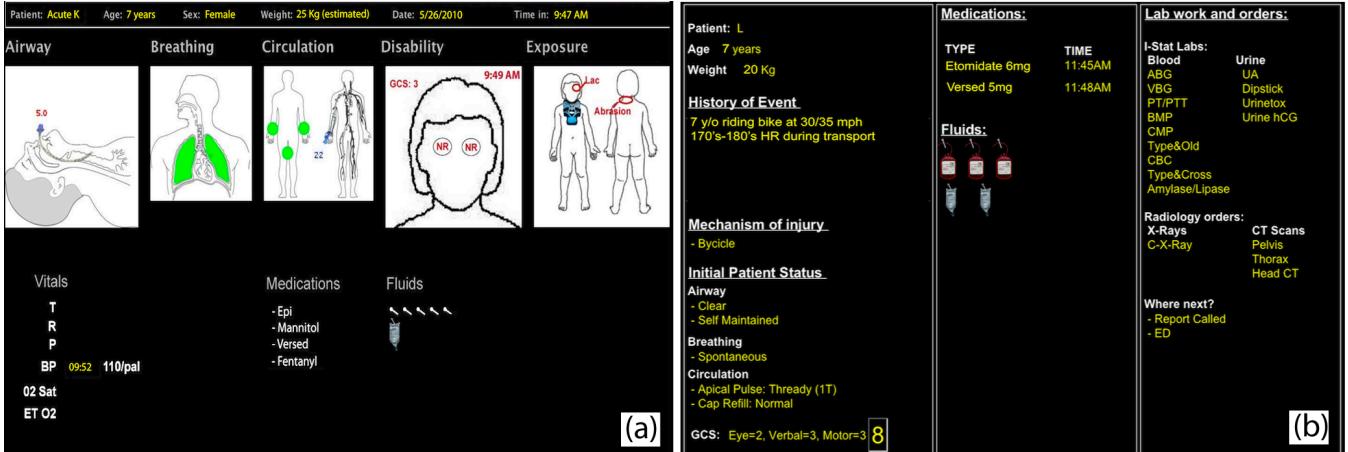

assigned to an experienced nurse who records the information on a paper flowsheet. The recording task is demanding and requires simultaneous attention to several information sources. Despite the challenges, we noticed that the flowsheet provided limited, but important support for trauma teamwork. The multiple-page flowsheet was usually spread open across a table, allowing easy navigation between sections and rapid data entry. The document also helped the recorder manage the process by allowing quick detection of missing information. Missing items usually implied skipped tasks and recorder's requests for these items often prompted the team to comply with the protocol.

## Design Requirements

Findings from field research suggested several preliminary requirements for designing the TraumaPen system.

The dynamic nature of trauma teamwork and a multitude of information sources and information types suggested that complete and accurate documentation using current computer data entry interfaces would be difficult. Although appealing as a solution, electronic medical record systems and tablet PCs have been found to slow down work processes in other medical and time-critical settings [6,10]. Additional challenge includes interacting with computers for information access while having hands and eyes busy with the main task of patient care. These findings led us to explore the ways in which the paper and digital world could be bridged to support situation awareness while preserving the benefits of using pen and paper.

Our studies also pointed to the need for external memory aids to support rapid acquisition and processing of information needed for decision making. Although paper-based flowsheet contains relevant patient information, it is inconvenient to access and difficult to lookup. We believed that displaying critical patient information using peripheral, large wall displays could facilitate information flow from *providers* (those who acquire information) to *seekers* (those who use the acquired information to make decisions), while also enabling quick information absorption at a minimum interference with the team's focus of attention—the patient.

**Figure 2: Two versions of the TraumaPen display design. (a) Initial display design based on findings from field research. (b) Redesigned display based on focus-group discussions with trauma team members.**

Furthermore, our studies suggested augmenting the role of the nurse recorder who, in addition to archiving, helps manage the resuscitation process by providing feedback to the team. The nurse recorder already captures information from the environment that is difficult to capture using automated techniques such as radio frequency identification (RFID) technology, computer vision or speech recognition. Although used successfully in some environments, these technologies are not ready yet for the noisy, crowded and dynamic setting of the trauma bay. For instance, patient findings obtained through palpation or visual assessment are verbally reported and then manually recorded; speech recognition capture is currently not feasible. Based on these findings, we concluded that the recorder could serve as a proxy for displaying up-to-date information for the team as he or she performs real-time documentation.

Finally, our studies identified the most frequently needed information types and showed how the use of information changed over the course of resuscitation. Trauma flowsheet contains many data elements, some of which are not critical to real-time decision making. Displaying the entire flowsheet as-is would clutter the display and make the information hard to access. This finding led us to consider displaying only the most frequently sought information.

### TRAUMAPEN SYSTEM PROTOTYPE

The TraumaPen system consists of two components: a digital pen and a large wall display. The purpose of the digital pen is to capture and store recorded information for presentation on the wall display, and for archiving. The purpose of the wall display is to present a selected set of recorded items in real time, as the recorder captures information on paper.

The system is based on the Anoto DP-201 digital pen that interfaces with the trauma flowsheet. The flowsheet is printed on standard paper layered with the Anoto dot-pattern that enables the pen to capture user's writing. The software is based on the iPaper/iServer framework for

capturing and processing paper-based information [14], and a novel toolkit for real-time data display. We selected data elements for capture and display using the frequency of queries during resuscitation. Selected fields on the paper flowsheet were then made "interactive" so that writing or making a checkmark captured and rendered the data in real-time on the wall display. Information is currently recorded using either checkboxes or freeform text (Figure 1). Our system supports both input modes: checkboxes are mapped directly onto the corresponding choices and stored as part of the TraumaPen data model, while freeform text is first processed by Intelligent Character Recognition software and then mapped onto corresponding entries in the data model. The data from the pen is transmitted wirelessly to a computer connected to the wall monitor for immediate processing and real-time display.

### Interactive Display for Supporting Situation Awareness

The interactive wall display (Figure 2(a)) was designed to show the most frequently sought information by trauma team members, as found during field research. This initial design of the display was also screened by collaborating physicians to ensure that the displayed information is consistent with resuscitation protocol. The display included the following information:

The very top section of the display in Figure 2(a) includes patient demographics such as age and weight. As we have found in our field studies, demographic information is needed throughout the event for administering fluid or medications, and interpreting vital signs.

The middle section presents patient status and findings from physiological evaluations during different stages of the primary survey. For example, the finding "breath sounds equal bilaterally" from step B (Breathing) is shown by green-colored lungs. Given the limited screen real estate and to enable quick identification and absorption of the critical information, we used graphical representation and color-coding for displaying primary survey findings [18].

The bottom section presents vital signs (temperature [T], respiratory rate [R], heart rate [P], blood pressure [BP], oxygen saturation [ $O_2$ Sat] and exhaled  $CO_2$  [ETO<sub>2</sub>]), administered fluids, and administered medications. For each vital sign, we displayed the latest value and the time it was recorded; for each administered medication, we displayed medication type; and for each bag of administered fluid (including blood), we displayed an icon of a fluid bag.

### PROTOTYPE EVALUATION IN THE TRAUMA BAY

To explore how coupling digital pens with wall displays can support situation awareness of trauma teams, we evaluated the TraumaPen prototype in two studies using a series of focus groups and simulation sessions with trauma team members. The goals of these studies were threefold. First, we wanted to assess the feasibility of using current documentation for real-time presentation. Second, we sought to open a discussion with trauma team members about the system's positive and negative aspects. Third, we used the focus groups and simulations to gather additional design requirements. More specifically, we sought to answer the following research questions:

1. To what extent will the added task of documenting for real-time display affect the recorder's work patterns?
2. To what extent will the current documentation practices affect real-time data presentation?
3. To what extent will the display support situation awareness during resuscitation?
4. Will the character recognition work well for real-time data capture and presentation in the trauma bay?

To conduct evaluation studies, we returned to our second research site—pediatric trauma center in the mid-Atlantic region. Both studies were approved by the hospital's IRB as an exempt research protocol. Below we describe methods and present findings from both studies.

### Study 1: Initial Prototype Evaluation

#### Methods

We first evaluated the TraumaPen prototype with trauma nurses and team leaders using focus groups: two with fourteen nurses (seven in each) and one with four senior surgical residents. We started with nurses and team leaders because we saw them as the primary users of our system: nurse recorders capture information for real-time display and team leaders use the display for information access and decision making. We used homogeneous focus groups to allow for in-depth discussion of design issues. Because of differing places of each group in the medical hierarchy, we felt we would obtain better feedback using this approach.

Each focus group lasted an hour and involved playing a 5-minute video about the system at the beginning of each session, followed by discussion. The video told a story about an injured child brought to the center and followed a typical resuscitation scenario including pre-hospital report,

evaluation, and treatments. We focused on presenting changes on the display as the scenario evolved and as the nurse documented the events. A video-in-video showed a flowsheet close-up with a hand recording the information. We believed this strategy was an effective design approach because it helped trauma team members match their domain knowledge with a future design of the system in the context of their work. Group discussions primarily focused on answering the first three research questions. All discussions were audiotaped and transcribed. To analyze the data, we used an open coding technique to identify recurring themes and issues about the system and its feasibility. We next present our findings organized by the two user groups.

#### *Findings from Focus Groups with Nurses*

Trauma nurses thought that digital pen technology was appropriate for documentation because it seemed consistent with their current work practices. Displaying evaluation steps and findings was perceived as beneficial to the team. Nurses felt that this information would help the team know immediately what evaluation steps have been completed:

*"It gives everybody a visual, it helps us make sure we don't miss anything and keeps us on track, like, we haven't checked pupils, ok let's check them now." (Nurse3)*

The system was also perceived useful in ensuring that the information is documented accurately:

*"This is going to make people more sensitive to making sure they document things appropriately and update vitals regularly. If a surgical resident looks up and see things we documented inappropriately, he can then tell us 'hey, that wasn't what I found or reported.'" (Nurse7)*

Information about administered medications and fluid was also found helpful. The nurses felt that times for each administered medication should be displayed to enable easier tracking and timing of subsequent doses. They also suggested including details about mechanism of injury to accommodate team members joining in late.

The nurses, however, expressed two main concerns about the TraumaPen system. First, they felt that displayed information would not be up-to-date as they often alternate between documenting different data elements. For example, they might not record patient demographics upon hearing the report because they might be documenting findings from the primary survey at that point. Or, they might wait until the end of physical assessment to confirm the findings:

*"For someone who is recording, there is so much going on, so much other verbal conversation that sometimes we do not hear clearly the surgical resident who is doing the assessment, so we first collectively listen what the findings are and then touch base with physician, who is giving me that report, at the very end of the secondary assessment, and we go over the assessment to make sure I captured everything accurately." (Nurse2)*

Second, there was a concern about displaying changes in the patient status. Because the patient's status may change rapidly, it is important to make these changes visible on the display. As the nurses pointed out, changes in patient condition after the primary and secondary survey had been completed are now documented in progress notes, a freeform text section in the flowsheet where nurses present a narrative of events. The structure of progress notes vary from nurse to nurse, which may pose additional challenges for detecting and recognizing updates in patient conditions.

#### ***Findings from Focus Groups with Trauma Leaders***

In contrast to nurses, surgical residents thought that having findings from primary survey displayed graphically would not be useful. They explained that this information could be easily obtained by just looking at the patient:

*"Looking at the display and seeing a tube drawn on the face and looking down on the patient and seeing a tube in the mouth is about the same." (Resident2)*

They instead suggested putting emphasis on patient demographics, mechanism of injury and initial evaluation findings to prevent interruptions by latecomers and others who missed the pre-hospital report, which is important in making the initial decision about the patient treatment:

*"Patient name, mechanism of injury, vital signs in the field and on arrival, GCS score and then initial findings from ABCD is about all that you are going to need on that board that anybody who walks in that room will need to know." (Resident3)*

The residents also found information about medications and fluids useful. They explained that tracking administered medications and fluid is often difficult due to the noise and poor communication in the trauma bay:

*"If you are a trauma leader, all you need up there is age, mechanism, so that people can figure that out, and medications and fluids that have been given, like a tally... having an active record of how much fluid has been given so that you can just look up and see, and see what medications have been given." (Resident1)*

Similar to nurses, team leaders expressed a concern with the system's ability to display changes in patient status:

*"Updating information on the board is important because things change rapidly, especially with kids, they will compensate for as long as they can, but they can suddenly crash, and if the board still shows that everything is fine, that is going to be a problem." (Resident3)*

Finally, the residents thought that the display should present patient management information including blood work orders, x-ray and CT-scan orders. This information is needed by staff who place orders and frequently interrupt surgical leaders when asking about patient management:

*"Other people need to know what x-rays and labs need to be ordered, because one of the main things that I have issues with is that you need to tell your orders to five people, but if you tell it to the charge nurse and she writes down 'basic trauma labs' and boom, it says 'basic labs' up there, so anyone can walk in and see that's the labs they want and then they start working on it as opposed to us having to tell repeatedly several times." (Resident2)*

#### **Design Refinements Based on User Feedback**

Using the findings from focus groups, we redesigned the TraumaPen display as follows (Figure 2(b)). First, we removed graphical representation of patient findings during primary survey. Although nurses thought this information would be beneficial to the team, we mainly focused on the feedback from surgical residents who are the key users of the display. As team leaders and decision makers, surgical residents will be looking at the display for information access and quick absorption of critical patient information. An additional reason for abandoning graphical display was the perceived difficulty of automatic detection of and inference about changes in the patient status from freeform progress notes. Our redesign still included findings from initial patient evaluation because they are captured using checkboxes and easily transferable to the display. We also included information about the mechanism of injury (captured by checkboxes) and the event history (captured by freeform text). Together with initial evaluation findings, this information comprises the left pane in Figure 2(b). The middle pane contains information about medications and fluids. Following nurses' and residents' suggestions, we included the time and dosage for each administered medication. The bottom section of the middle pane is intended for future trending of vital sign data. The right pane presents patient management information, including lab, x-ray and CT-scan orders.

#### **Study 2: Simulation Evaluation**

With a redesigned display and a semi-functioning system, we conducted a follow-up evaluation study. The study involved training sessions with nurses and deploying the system in two simulation scenarios with two trauma teams.

#### ***Training Sessions: Methods***

We first conducted training sessions with six trauma nurses. The primary goal of these sessions was to prepare nurses for simulations by training them on the TraumaPen system. These sessions provided an opportunity to further assess the extent to which using the system impacts nurses' work and how current documentation practices may affect real-time data presentation. We also ran initial tests on character recognition using nurses' handwriting. Each session lasted 30 minutes and consisted of: (a) a brief introduction to the system, (b) simulation of the documentation process by watching a 10-minute video of a real trauma simulation and by using the digital pen, and, (c) discussion about nurses' experiences. The nurses were seated at a desk, with the

TraumaPen display positioned in front of them and simulation video projected on the wall on their right-hand side. During the recording activity, we observed nurses' interactions with the pen and whether they were looking at the display. The current design of the flowsheet was not altered for the study. The only modification was overlaying the Anoto dot-pattern on the document. Each session was audiotaped and transcribed. We again used the open coding technique to identify major themes about the system's use and its impact on nurses' work.

#### **Training Sessions: Findings**

All six nurses reported that using the digital pen felt like using a traditional pen. As one of the nurses commented: "*It works as normal pen, the documentation part isn't going to be different if we can use it like we normally do.*" One nurse, however, noticed that the digital pen might affect her charting because "*you'll have to be more careful about not just circling something, it can look OK on paper but it can be off on the screen.*"

One of our concerns was how distracting the display would be for nurses as they performed the documentation task. Our expectation was that nurses would continue to focus on the documentation and would glance at the display only occasionally or not at all. During training sessions, nurses emphasized that documentation requires their absolute attention and does not leave much time for looking at the display. A nurse explained:

*"I didn't look up and I wouldn't because things are moving so fast in there that I am constantly keeping up on [the form]. I was so focused on listening and writing, but if I were in a real trauma I would have to attend to million things at once and I probably wouldn't have a chance to look up until the primary survey was over."*

We noticed however that one nurse occasionally glanced at the display. When asked about the reasons for looking at it, this nurse commented, "*I was just interested if it was picking up what I was writing.*" This finding revealed that nurses might look at the display to check for correctness of the displayed information.

Training sessions again revealed the issue of potential delays in displaying up-to-date information that was first raised during focus groups. As one of the nurses described, they often record information with a delay:

*"I would go back and forth, and this [mechanism of injury], a lot of times I don't even write the history until I actually know what happened... by the time paramedics finish their report, I am already recording my first set of vitals, so I'll just remember the report, focus on what's going on, and then go back and write down the report."*

Still, we observed that some information is recorded at the time it is reported. Examples include medications, a neurological scale for assessing consciousness (GCS), and vital signs. Nurses pointed out that despite variability in

their work, documentation depends mostly on what they hear or see. Communication failures and skipped evaluation steps may impact when the information is documented.

Finally, the training sessions pointed to problems with handwriting recognition and information accuracy. As all six nurses engaged in recording activity, we observed that the system was not recognizing their handwriting properly. Handwriting recognition was not only a problem for medical terms (e.g., medication names), but also for proper English words (e.g., house fire) and numbers. Handwriting recognition raised concerns about accuracy of the displayed information. A nurse explained:

*"If for medications it shows 'phantoms' instead of 'etomidate' or '16mg' but we actually gave '6,' it's a big deal... especially things like kilos and things like that, we'll have to check because if it's inaccurate up there, then that can be a real problem."*

Based on our findings from training sessions we decided to modify the system before doing simulations with trauma teams. Because handwriting recognition emerged as the most prominent issue, we replaced recognition with capturing and displaying an image of handwritten text for all active, freeform fields. We felt this modification would improve accuracy of the displayed information and help trauma teams better perceive the potential of our system in supporting situation awareness.

#### **Simulation Sessions: Methods**

We further evaluated the TraumaPen prototype in the context of simulated trauma resuscitation, with a total of 13 trauma team members. Simulations have commonly been used to evaluate trauma resuscitation performance. While realizing that a patient simulator is being used, participants frequently "suspend their disbelief" and perform in a manner similar to actual clinical scenarios [13]. The first simulation involved an attending surgeon, a junior surgical resident, and five nurses, two of whom participated in earlier training sessions. The second simulation involved an attending surgeon, two pediatric nurse practitioners who often assume a physician doer role, one senior- and one junior surgical resident, and one TraumaPen-trained nurse. Both sessions involved the same clinical scenario and lasted about 10 minutes each. Our goals here were to obtain additional feedback using heterogeneous focus groups in the semi-real environment of the trauma bay (Figure 3).

To display awareness information, we connected our system to two 42" wall mounted-monitors visible to team members at the head and foot of the bed. Both displays showed the same information. Sessions were videotaped using two cameras and microphones to track who among the participants looked at the display and when during simulation. The nurse recorders were given the digital pen and Anoto-patterned flowsheets. At the beginning of each session, we briefly introduced the system. Upon completion of each simulation scenario, we conducted a focus group

**Figure 3: Simulation setting, arrangement of trauma team members, and the TraumaPen display. Second display (not shown) is mounted on the wall opposite to the first display.**

discussion with participants for about 15 to 20 minutes. Discussions were audiotaped, transcribed, and analyzed in the same manner as reported earlier.

#### *Simulation Sessions: Findings*

We observed that team members frequently glanced at the display during the simulation sessions. Glancing at the display mostly occurred in the first five minutes, while the teams performed primary survey, patient intubation, and fluid administration. For example, in the first session, when the team leader ordered a liter of fluid, the primary nurse first looked at the monitor and then turned to the recorder, inquiring, “*I am sorry, I can’t read his weight, what is it?*” Or, in the second session, when the recorder asked about the fluid rate, all team members glanced at the monitor. The nurse recorders did not look at the display; they were busy documenting and communicating with other team members about patient information.

In current practice, obtaining patient information requires looking around or querying the recorder, or the person who owns the information. Our preliminary data from simulations showed promise in using information displays for faster access to patient information. A quick glance at a well-designed display takes less time than engaging in verbal exchange with another team member.

Simulation sessions also confirmed some of the limitations of the TraumaPen system. Although we replaced character recognition with an image of handwriting, we observed that team members had trouble reading the handwritten text in the images. First, text in the images was small and illegible from distance. Second, readability of text now depended on readability of the recorder’s handwriting. Although both recorders had neat handwriting, the images were difficult to read and raised concerns about the ability to capture and effectively display handwritten information.

#### **DISCUSSION**

Findings from evaluation studies in a pediatric trauma center confirmed that there is a need to support situation

awareness during trauma resuscitation. Through an iterative design and evaluation process that involved trauma team members, we were able to better understand trauma teams’ information needs as well as documentation practices that are critical to reliable functioning of the TraumaPen system. Although team members’ comments and interactions with the TraumaPen showed promise for digital pen technology in this setting, the studies also revealed several challenges for use in such a complex and safety-critical domain.

#### **Added Task of Documenting for Real-Time Display**

One of the research questions we sought to answer was to what extent would the added task of documenting for real-time display affect the recorder’s work patterns. Results from training sessions and simulations showed that nurse recorders primarily focused on documenting and rarely looked at the display. Nurses also felt that the digital pen did not affect their current way of recording information. These findings suggest that having the recorder as a proxy for displaying up-to-date patient information can be an effective way of supporting trauma teamwork.

Still, our studies raised an important issue related to nurses’ use of the system. As we observed during training sessions, nurses might need to look at the display frequently to check the *correctness of displayed information*. Because frequent glances at the display distract nurses from their primary task, the challenges of ensuring the correctness of information and its appropriate display should be addressed. One positive aspect of displaying recorded information for the whole team is that the task of checking for correctness is now distributed among team members. In addition to helping trauma teams, distributing the task of checking for correctness may also help improve the documentation process. Another solution could be adding some form of feedback or alerting mechanism to allow timely response to incorrect or inappropriately displayed information. As team members repeatedly emphasized, displaying incorrect information would make the system useless or detrimental.

#### **Real-Time Documentation vs. Real-Time Presentation**

Our evaluation studies revealed an apparent disconnect between real-time documentation and presentation. Some information is captured as observed or reported, while other information is held in memory and recorded at a later time. Although we initially believed that real-time documentation was predictable, our study uncovered this discrepancy by introducing a novel use of the recorded information: in addition to its traditional use for archiving, it was now being used to support situation awareness. We believe that this finding is valuable when considering other technologies in dynamic work settings. The order in which the information is documented may impact the design of such technologies and should be considered.

Even so, our findings showed that documentation process is not random. Some information types are recorded immediately and in the order they are received and can thus

be displayed using the TraumaPen system. Our future work will examine the prioritization of information documenting in greater detail and identify information items that are suitable for digital pen technology.

The studies also showed the importance of allowing frequent updates or corrections of the displayed information. As reported by trauma team members, patient conditions change rapidly. For the system to be useful, it must present up-to-date information and the time it was last updated. When a nurse makes a mistake on the flowsheet, he or she strikes the data through and writes the correct information next to it. Observed changes in the patient condition after the initial evaluation had been completed are now documented in freeform progress notes. Future prototypes of the TraumaPen should detect corrections on the flowsheet and automatically infer important information from progress notes that is pertinent to patient conditions.

### **Too Much Information, Too Few Displays**

Our study suggests that supporting situation awareness in trauma resuscitation may require several displays for different information types and for different users. As seen from participants' comments, not all information is equally important to all team members. Information about patient findings, administered medications and fluids helps support situation awareness of decision-makers, while information about mechanism of injury or lab orders helps latecomers and supporting staff. Our findings also showed the differing views of nurses and surgical residents on the usefulness of graphical representation of physical assessment. As documenters, nurses viewed this information as a helpful tool in providing a quick overview of what tasks have been completed and what tasks were skipped. Conversely, trauma leaders perceived this information extraneous; being at the patient bedside and supervising the process, they are able to see the patient's current condition.

To adequately meet the goals of all trauma team members, we suggest having three displays positioned throughout the room, each with a different set of information types. Trauma team leaders, including attending physicians and surgical residents, would benefit from a peripheral, larger display that shows information needed for decision making, such as patient demographics, initial vital signs, and medications and fluid administered. To support the information needs of latecomers, another display could be positioned near the entrance to the room to present information about mechanism of injury and completed evaluation tasks along with findings. A smaller display in the administrative area could show patient management information, such as laboratory and radiology orders for supporting staff. How to array information over multiple displays requires careful consideration about what, where, and how information is displayed [15]. In our future work, we will continue to experiment with different information items to determine whether displaying them has a positive impact on trauma teamwork.

### **Handwriting Recognition in Dynamic Work Settings**

The last research question examined the extent to which information systems can rely on handwriting recognition in dynamic work settings such as trauma bay. Despite promising evidence [6,8], our findings showed that both the speed with which nurses document and the use of medical terms make character recognition challenging in this domain. Even our alternative solution of using an image of handwritten text showed only limited promise. Nurses' handwriting styles vary, posing additional challenges to presenting handwritten information.

This finding raises an important question: If nurses' handwriting is difficult to read on the screen, how easy or difficult it is to read on paper? Conversations with nursing management revealed that some flowsheets are difficult to decipher because of nurses' handwriting. It may be then that documentation for public display presents an opportunity to motivate improving nurses' handwriting. Because recorded information is also visible to the entire team, it may lead nurses to write more legibly. However, the idea of changing nurses' handwriting raises several issues. Improving character recognition alone is a technological fix and would not impact nurses' work. In contrast, asking nurses to write more clearly represents a socio-technical change. While our goal is to introduce technology with minimal disruption to nurses' work, we also must evaluate the many cost-benefit tradeoffs of change. For example, asking nurses to write in capital letters may be less disruptive than asking them to document each data point in real time. Evaluating such tradeoffs is crucial in designing for complex, safety-critical domains.

Our findings also showed that not all fields on the flowsheet are optimally designed for real-time capture and display. The digital pen worked best for displaying items captured through checkboxes. To display handwritten information using the digital pen, both redesigning of the flowsheet and changing nurses' work practices may be needed. Alternatively, handwriting can be computationally smoothed and scaled to increase its readability before display.

### **CONCLUSION**

We have designed, built and studied a prototype TraumaPen system to support situation awareness in the fast-paced setting of the trauma bay. Although our findings show the benefits and feasibility of our approach, they also highlight challenges in designing technology for the complex, safety-critical domain of trauma resuscitation. Using an incremental approach to system design, we identified important requirements for and challenges to introducing technologies in this domain. We realize that changes in practice will be needed to exploit technologies for supporting trauma teamwork. Most important, our design approach and evaluation methods allowed us to discover early in the process that some of our initial design solutions were not appropriate. We believe that findings

from this study will offer useful insights for supporting design work in other safety-critical domains.
